Reducing the Heat Island Effect: A Mathematical Model of Green Roof Design
Jing Hong1, D Michael Utzinger2
1 Rivion, Milwaukee, WI, USA
2Department of Architecture, University of Wisconsin - Milwaukee, Milwaukee, WI, USA

Abstract
Green roofs ease the heat island effect. Optimizing green roof design helps achieve this goal more efficiently. This paper proposes two energy models of green roofs to estimate surface temperature, and validates them with experimental evidence.

Architects and engineers optimizing their green roof design can use the proposed energy balance models in any equation-solving software. The mathematical models were validated with measured soil temperatures taken from the green roof at the University of Wisconsin – Milwaukee’s Golda Meir Library. The energy balance model explains how surface colour, soil depth and plant types affect the surface temperature of a green roof. The green roof surface temperature can be reduced by lighter surface colour, shallower soil depth, and plants with lower internal leaf resistance and larger leaf size.

Key Innovations
- Allow a green roof to be simulated independently without developing the whole building performance.
- Stand-alone equation that can be scripted in any equation-solving platform.

Practical Implications
The proposed energy models can be independently implemented by architects and engineers to optimize their green roof design in any equation-solving software or component-based algorithmic modelling software. For example, MATLAB, Grasshopper+Python/MATLAB, TRNSYS+MATLAB, and so on.

Introduction
Green roofs have many potential benefits. Reducing the urban heat island effect by lowering the roof surface temperature is one of the major reasons that developers widely apply green roofs to their buildings. The heat island effect is caused by urban sprawl. Green roofs can help to reduce it (Susca, Gaffin & Dell’Osso, 2011). For the well-insulated buildings, the impact of green roofs on building energy performance is minimal (Jaffal & Belarbi, 2012). Therefore, a green roof performance is not necessarily simulated with the whole building energy performance. The most widely used green roof model is developed and integrated in EnergyPlus by D.J. Sailor (2008). However, the green roof component built in EnergyPlus cannot be separately run on other platforms. The goal of this research is to create an open-source and simplified heat transfer model of a green roof to estimate the roof’s surface temperature. The model has green roof materials and assemblies as parameters and climate data as inputs. However, weather conditions and building characteristics are viewed as exogenous, as they are not elements of green roof design. Only variable elements of green roofs are studied here.

In the proposed energy model, the calculation of radiation, convection and evaporation effects on surface temperature are simplified to use fewer unknown variables. For that reason, this model only requires basic weather data and an initial soil temperature reading to estimate the green roof surface temperature in any equation-solving program.

Green roof mathematical model
Mathematical models can help build simulation programs and explore the performance of green roofs in energy saving and water retention. A mathematical model of a green roof consists of two parts: The energy balance model and the mass balance model. Based on the Law of Conservation of Energy and Mass, the heat and mass flow in green roofs will always follow:

\[ \Delta q = \text{The difference of humidity between the surface and the air, kg/kg} \]
\[ e = \text{Water vapor pressure Pa} \]
\[ P = \text{Total atmospheric pressure Pa} \]
\[ \Delta G = \text{Soil heat storage, J/m}^2 \]
\[ U_{blg} = \text{Existing roof U-value, W/m}^2\text{K} \]
\[ T_{blg} = \text{Building surface temperature, K} \]
\[ h_{c,g} = \text{Thermal resistance of air space between canopy and ground, } 4 \sim 5.67 \text{ w/m}^2\text{°C} \]
\[ d_1 = \text{The saturation density of water vapor in the leaf intercellular air spaces as a function of leaf temperature, kg/m}^3 \]
\[ d_a = \text{The saturation density of water vapor in the air as a function of air temperature, kg/m}^3 \]
\[ h = \text{Relative humidity of the air, } \% \]
\[ r_i = \text{Internal leaf resistance, 100~2000 s/m} \]
\[ r_a = \text{Surface boundary-layer resistance} \]
\[ \omega_a = \text{Humidity ratio, kg/kg} \]
\[ \rho_a = \text{Dry air density, kg/m}^3 \]
\[ B = \text{0.622 for air, kg/kg} \]
\[ P_w = \text{Saturated water vapor pressure, mbar} \]
\[ P_{w,l} = \text{Water vapor pressure on leaf, mbar} \]
\[ P_{w,a} = \text{Water vapor pressure of air, mbar} \]
\[ P_{total} = \text{Ambient total pressure, mbar} \]
\[ A = 6.116441 \text{ for water between -20°C ~ 50°C} \]
\[ \Delta z = \text{Distance between two points} \]
\[ T_{soil} = \text{The soil temp. at the beginning of the time step, K} \]
\[ T_{surf} = \text{The soil temp. at the end of the time step, K} \]
\[ \rho_d = \text{Dry bulk density, kg/m}^3 \]
\[ c_d = \text{Specific heat capacity of dry soil, J/kg·K} \]
\[ c_w = \text{Specific heat capacity of water, J/kg·K} \]
\[ w = \text{Water content, kg/kg} \]
\[ m = 7.591386 \text{ for water between -20°C ~ 50°C} \]
\[ T_n = 240.7263 \text{ for water between -20°C ~ 50°C} \]
\[ T = \text{Ambient temperature, °C} \]
\[ RH = \text{Relative humidity} \]
\[ W = \text{The dimension at right angles to the width of a leaf, m} \]
\[ D = \text{Width of a leaf in the direction of the air flow, m} \]
\[ k_2 = 200 \text{ s}^{1/2}/\text{m} \]

\[ \text{Input – Output = Energy or mass storage} \quad (1) \]

In the energy balance model, as shown in Figure 1, the heat transfer approaches include solar radiation, sky radiation, heat convection, heat conduction and heat storage in the soil.

In the mass balance model, as shown in Figure 1, which is also the water balance, the water flows include precipitation, evapotranspiration, condensation, drainage and retention.

\[ Q_{solar} + Q_{rad} + Q_{cond} + Q_{conv} - Q_{evap} = 0 \quad (2) \]

Then we have,
\[ Q_{solar} = I_{solar} \Delta t \alpha_{solar} \quad (3) \]
\[ Q_{rad} = \varepsilon_{surf} \sigma \Delta t (T_{sky}^4 - T_{surf}^4) \quad (4) \]
\[ Q_{cond} = \frac{k_s}{d} \Delta t (T_{soil} - T_{surf}) \quad (5) \]
\[ Q_{conv} = h_{c} \Delta t (T_{air} - T_{surf}) \quad (6) \]
\[ Q_{evap} = \bar{z} E \Delta t \quad (7) \]

Through onsite measurement, it is easily found that the surface temperatures of a bare soil and a vegetation-covered surface are different. Therefore, the energy balance model of a green roof should be separately developed for a bare soil and a vegetation-covered green roof.

Bare Soil Energy Balance: Surface Temperature
The energy transfer flow of the bare soil is illustrated in Figure 2. The surface of the bare soil absorbs the solar radiation, absorbs or releases radiation from or to the sky, convects heat with the air on the surface, and then conducts the heat down to the soil and building. There is
The energy balance of the heat flux through the bare soil surface is as follows:

\[ I_{\text{solar}} \propto \varepsilon_{\text{soil,surf}}(T_{\text{sky}}^4 - T_{\text{surf}}^4) + h_c(T_{\text{air}} - T_{\text{surf}}) + \frac{k_s}{\varepsilon} (T_{\text{soil}} - T_{\text{surf}}) - \lambda E = 0 \]  

(8)

The average solar radiation can be measured or provided by the weather data, for example, TMY-3. Solar absorption \( \varepsilon_{\text{soil,surf}} \) is determined by the surface color.

The radiation between sky and surface is estimated by the emissivity function, the Stefan–Boltzmann constant, and the difference between the fourth powers of the sky and surface temperatures.

The emissivity of the moist soil can be estimated by the emissivity of the dry soil and the saturated soil:

\[ e_{\text{soil,surf}} = e_{\text{soil,dry}} + (e_{\text{soil,sat}} - e_{\text{soil,dry}}) x_F \]  

(9)

And \( T_{\text{sky}}^4 - T_{\text{surf}}^4 \) in Equation 8 can be expressed as:

\[ (T_{\text{sky}}^4 - T_{\text{surf}}^4) = (T_{\text{sky}}^2 + T_{\text{surf}}^2)(T_{\text{sky}}^2 - T_{\text{surf}}^2) = (T_{\text{sky}}^2 + T_{\text{surf}}^2)(T_{\text{sky}} - T_{\text{surf}})(T_{\text{sky}} + T_{\text{surf}} - 2T_{\text{surf}}) \]  

(10)

For two arbitrary surfaces that have close temperatures, an estimated average temperature \( T \) can be introduced to simplify the sky radiation heat transfer (Duffie & Beckman, 1980).

\[ 4T^3 = (T^2_s + T^2_f)(T_s + T_f) \]  

(11)

Since the surface temperature is close to the air temperature, we can get an approximate \( T \) using the average of sky temperature and ambient air temperature.

\[ T = \frac{T_{\text{sky}} + T_{\text{surf}}}{2} \]  

(12)

Then \( T_{\text{surf}}^4 - T_{\text{soil}}^4 \) can be expressed as:

\[ (T_{\text{surf}}^4 - T_{\text{soil}}^4) = 4T^3(T_{\text{sky}} - T_{\text{surf}}) \]  

(13)

Therefore, the energy balance for a node in the soil can be expressed as:

\[ I_{\text{solar}} \propto \varepsilon_{\text{soil,surf}} + 4 \varepsilon_{\text{soil,surf}} \sigma T^3(T_{\text{sky}} - T_{\text{surf}}) + h_c(T_{\text{air}} - T_{\text{surf}}) + \frac{k_s}{\varepsilon} (T_{\text{soil}} - T_{\text{surf}}) - \lambda E = 0 \]  

(14)

The method of estimating sky temperature \( T_{\text{sky}} \) is a function of the dew point temperature, dry bulb temperature, and number of hours since midnight \( t \) (Berdahl & Martin, 1984).

\[ T_{\text{sky}} = T_{\text{air}}[0.711 + 0.0056 T_{dp} + 0.000073 T_{dp}^2 + 0.013 \cos(15\pi t)]^{0.25} \]  

(15)

The convection heat transfer happens on the surface boundary, and it can be estimated as a function of the convection coefficient and the difference between the air temperature and surface temperature. The convection coefficient, \( h_c \), can be estimated with a given wind speed (Watmuff et al., 1977). And this wind speed, \( V \), is monitored by the weather station.

\[ h_c = 2.8 + 3.0V \]  

(16)

The effective thermal conductivity \( k_e \) can be estimated by the idealized models of heat flow through a unit cube of moist soil (Farouki, 1982).

\[ \frac{1}{k_e} = \frac{x_s + x f}{k_s + k_f} \]  

(17)

\( x_f \) and \( x_s \) are monitored by the weather station. \( k_s \) and \( k_f \) can be estimated by tests or found in the engineering property charts.

For the water retained in the topsoil, the evaporation can be estimated by Equation 18 (Oke, 2002):

\[ E = \rho_{\text{air}} CV \Delta \bar{q} \]  

(18)

The air density is calculated using the built-in function of the Energy Equation Solver (EES) with a known dry bulb temperature, dew point temperature and air pressure, as provided by the weather stations.

The humidity can also be calculated with a known temperature and pressure (Gates, 2012):

\[ q = \frac{0.622e}{P - 0.379e} \approx \frac{0.622e}{P} \]  

(19)

Tetens’ formula for temperatures above 0°C define the water vapor pressure as indicated below (Monteith & Unsworth, 2007):

\[ e = 0.61078 \exp \left( \frac{17.27T}{T + 237.3} \right) \]  

(20)

Therefore, the evaporation rate can be estimated by the soil temperature and ambient air temperature:

\[ E = \rho_{\text{air}} CV \frac{0.622e}{P} 0.61078(\exp \left( \frac{17.27T_{\text{soil}}}{T_{\text{soil}}+237.3} \right) - \exp \left( \frac{17.27T_{\text{air}}}{T_{\text{air}}+237.3} \right) \) 

(21)

To solve the equation above, the surface temperature \( T_{\text{surf}} \) can be estimated as follows:

\[ T_{\text{surf,soil}} = \frac{I_{\text{solar}} \propto \varepsilon_{\text{soil,surf}} + 4 \varepsilon_{\text{soil,surf}} \sigma T^3 \varepsilon_{\text{soil,surf}} h_c T_{\text{air}} + \frac{k_s}{\varepsilon} (T_{\text{soil}} - T_{\text{surf}}) - \lambda E}{h_c + 4 \varepsilon_{\text{soil,surf}} \sigma T^3 + \frac{k_s}{\varepsilon}} \]  

(22)

**Bare Soil Energy Balance: Soil Temperature**

The surface temperature, \( T_{\text{surf,soil}} \), can be calculated by the equation 22 when the soil temperature is known. However, in most cases, soil temperature thermometers are not installed for green roofs. If the soil temperature is unknown, an energy balance in the soil can be derived as a function of the heat conduction between the soil surface and building surface, and the heat storage.
\[ \Delta G = \frac{k_e}{d} T_{surf,soil}^i - T_{soil}^i + \left( \frac{1}{\frac{k_e}{d} + \frac{1}{U_{bldg}}} \right) (T_{bldg}^i - T_{soil}^i) \]  

(23)

The heat capacity of the soil will store heat. The heat storage between any two points of the soil is

\[ \Delta G = \int_0^z C_v \frac{dT}{dT} dz = \Delta z \cdot C_v \cdot \frac{T_{soil}^i - T_{soil}^f}{\Delta t} \bigg|_{0-z} \]  

(24)

\[ C_v = \rho_d (c_d + wC_w) \]  

(25)

Combining the equations above, the energy balance of the soil temperature is as below: 

\[ \frac{2dC_v (T_{soil}^{i+1} - T_{soil}^i)}{\Delta t} = \frac{k_e}{d} (T_{surf,soil}^i - T_{soil}^i) + \left( \frac{1}{\frac{k_e}{d} + \frac{1}{U_{bldg}}} \right) (T_{bldg}^i - T_{soil}^i) \]  

(26)

The soil temperature \( T_{soil}^{i+1} \) can be expressed as: 

\[ T_{soil}^{i+1} = T_{soil}^i + \frac{\Delta t}{2C_v d} \frac{k_e}{d} (T_{surf,soil}^i - T_{soil}^i) + \left( \frac{1}{\frac{k_e}{d} + \frac{1}{U_{bldg}}} \right) (T_{bldg}^i - T_{soil}^i) \]  

(27)

The \( T_{soil}^i \) from Equation 27 was replaced with the surface temperature Equation 22, achieving the following soil temperature equation:

\[ T_{soil}^{i+1} = \frac{\Delta t k_e}{2C_v d} (0.04 + 4\varepsilon_{soil,surf}^{i} (\frac{T_{sky}}{3})^{3} + \frac{h_c}{k_p} T_{air} - \lambda E) + \] \[ \frac{\Delta t}{2C_v d} \frac{k_e}{d} \left[ \frac{\Delta t k_e}{2C_v d} + \frac{1}{\frac{k_e}{d} + \frac{1}{U_{bldg}}} \right] \] \[ \left( \frac{2C_v d}{h_c + 4\varepsilon_{soil,surf}^{i} (\frac{T_{sky}}{3})^{3}} \right) - \frac{1}{1} T_{soil}^i \]  

(28)

\[ \lambda E = \lambda_{air} CV \frac{0.622 e}{p} \cdot 0.61078 (\exp (\frac{1787T_{air}}{T_{air}+257.3}))- \exp (\frac{1727T_{soil}}{T_{soil}+257.3}) \]  

(29)

Note: The \( T_{soil}^i \) in Equation 28 is in Kelvin units, but the \( T_{soil}^i \) in Equation 29 is in Celsius units.

Vegetation-Covered Soil Energy Balance: Surface Temperature

Compared to the uncovered bare soil, the vegetation-covered green roof includes the plant transpiration and extra heat transfer between the vegetation and soil surface. The energy transfer flow of the vegetation-covered surface is illustrated in Figure 3. The surface of the vegetation absorbs the solar radiation, absorbs or releases radiation from or to the sky, convects heat with the air on the surface, and then conducts the heat down to the air between the vegetation and soil surface, the soil, and the building. There is some heat stored in the soil during heat conduction.

\[ \Delta G = \frac{k_e}{d} T_{surf,soil}^i - T_{soil}^i + \left( \frac{1}{\frac{k_e}{d} + \frac{1}{U_{bldg}}} \right) (T_{bldg}^i - T_{soil}^i) \]  

(30)

\[ \frac{\Delta t k_e}{2C_v d} \left( \frac{\Delta t k_e}{2C_v d} + \frac{1}{\frac{k_e}{d} + \frac{1}{U_{bldg}}} \right) \left( \frac{2C_v d}{h_c + 4\varepsilon_{soil,surf}^{i} (\frac{T_{sky}}{3})^{3}} \right) - \frac{1}{1} T_{soil}^i \]  

(31)

The internal leaf resistance, \( r_i \), is between 100 and 2000 s/m depending on the plant type (Oke, 2002). To simplify the calculation, we assume the air density on the leaf and atmosphere are approximately the same. Therefore,

\[ d_1 \approx d_\omega = \omega d_a \rho_a \]  

(32)

The humidity ratio can be estimated as below (Oyj, 2013):

\[ \omega_a = \frac{B_{Pw}}{(P_{total} - P_w)} \]  

(33)

If low accuracy is allowed, a simpler formula of \( P_{w3} \) can be estimated as follows:

\[ P_{w3} = P_{w1} \cdot \frac{RH}{100} = A \cdot 10^{mT/237.3} \cdot \frac{RH}{100} \]  

(34)

\[ A = 6.116441 \text{ for water between } -20°C \sim 50°C \] \[ m = 7.591386 \text{ for water between } -20°C \sim 50°C \] \[ T_n = 240.7263 \text{ for water between } -20°C \sim 50°C \] \[ T \text{ Ambient temperature, °C} \] \[ RH \text{ Relative humidity} \] \[ P_w \text{ Saturated water vapor pressure, mbar} \] \[ \omega_a = k_2 \left( \frac{P_{w}}{P_{air}} \right)^{0.3} \]  

(35)

\[ k_2 \text{ is approximately } 200 \text{ s}^{1/2}/\text{m}. \]

The dimension of a leaf of the sedum plant is about 0.01m x 0.01 m, so

\[ r_a = 200 \times \frac{0.01^{2} \times 0.01^{3}}{P_{air}^{0.5}} \approx \frac{20}{P_{air}^{0.5}} \]  

(36)

Solving Equation 30 with Equation 31-36, the surface temperature of vegetation is
Vegetation-Covered Soil Energy Balance: Soil Temperature

Equation 37 can be used to predict the surface temperature on the vegetation of a green roof with the known soil temperature. Following the same derivation method of the bare soil temperature, we can achieve an energy balance with the function of the heat conduction between the vegetation surface and building surface, and heat storage in the soil:

\[
\frac{2\Delta C_P}{\Delta T_{\text{soil}} - T_{\text{soil}}} = \frac{1}{\frac{1}{k_e} + \frac{1}{h_c}} (T_{\text{surf,veg}} - T_{\text{soil}}) + \left( \frac{1}{\frac{1}{k_e} + \frac{1}{h_c}} (T_{\text{bidg}} - T_{\text{soil}}) \right)
\]

(38)

The \( T_{\text{surf,veg}} \) in Equation 38 was replaced with the surface temperature Equation 37, giving a soil temperature equation:

\[
\frac{\Delta T_{\text{soil}}} {2C_P} = \left( \frac{1}{\frac{1}{k_e} + \frac{1}{h_c}} \right) \left[ i_{\text{solar}} h_{\text{solar}} + 4k_{\text{veg}} h_{\text{surf}} (T_{\text{sky}}) T_{\text{air}} + \frac{1}{1-h_{\text{air}}} \right] \frac{\Delta t}{dt} + \frac{h_c + 4k_{\text{veg}} h_{\text{surf}} (T_{\text{sky}}) T_{\text{air}}}{1-h_{\text{air}}} \frac{\Delta t}{dt} + \frac{\Delta t}{dt}
\]

(39)

### Validation

The mathematical models of green roofs’ heat transfer are simulated using the numerical computing software, MatLab. The coefficients in the models were based on experiments, estimation and known measured results.

The validation data were measured from the Golda Meir Library’s green roof at University of Wisconsin – Milwaukee in 2014. To validate the energy balance model, the modelled soil temperature was compared with the measured one. At each point in time, Equations 28 and 39 were simulated in MatLab to calculate the soil temperature, and then compared to the measured data.

The root-mean-square deviation (RMSD) and the standard error (SE) of the differences were used as the criteria to investigate the errors. The modelled soil temperatures were validated with the measured ones from April to October 2014. For the bare soil surface, the sample mean of the difference is 0.5°C, RMSD=3.15°C and the SE is 0.0235. For the soil temperature beneath the canopy, the average difference of the simulation is 1.31 °C, RMSD=2.34 °C and the SE is 0.015.

To better illustrate the difference between measured and the simulated data, Figures 4 and 5 compare the calculated and measured soil temperature of bare soil and vegetation-covered soil in August 2014.

**Application of the Energy Model**

**Energy Flux Density**

With the surface temperature computed in MatLab, \( Q_{\text{solar}} \), \( Q_{\text{rad}} \), \( Q_{\text{conduction}} \) and \( Q_{\text{evaporation}} \) can be calculated using Equation 2-7. Figures 6 and 7 show the average hourly energy flux density in August 2014 for bare soil and vegetation-covered surfaces. When \( Q \) is positive, the surface is absorbing heat, and otherwise is losing heat.
The solar radiation, $Q_{\text{solar}}$, is the major heat source for both bare soil and vegetation-covered surface. In August, solar radiation appears from 6 a.m., increases to a peak in the afternoon from 13:00 to 14:00 (1 p.m. to 2 p.m.), and then decreases gradually toward sunset at around 18:00 to 19:00 (6 p.m. to 7 p.m.). In the simulation, I assumed the same absorption for both bare soil and vegetation-covered surfaces.

The diffusive radiation from the atmosphere, $Q_{\text{rad}}$ is negative throughout the day. That means the surface temperature is always higher than the sky temperature, which makes sense during summer.

The heat conduction, $Q_{\text{cond}}$, is negative during the day and positive during the night. That means, whether there is vegetation coverage, the soil is absorbing heat during the day and losing heat during the night. It also demonstrates that the heat is conducted down to the building through the soil during the day and released from the building through the soil at night.

**Temperature**

As shown in Figure 8 of the surface temperature comparison, the surface temperature changes reflect the change in solar radiation immediately. In the morning, the surface temperature increases more rapidly. Based on the rate of increase of temperature and solar radiation in the morning, we can see that the temperature increase is sharper than the solar radiation increase. This means that when the surface receives solar radiation in the morning, it heats up more quickly. After solar radiation peaks, the temperature starts to go down, but it does not reduce the surface temperature as much as it does in the morning. The thermal inertia, which is also the heat capacity of the surface, is the main reason for this phenomenon.

Figure 6. The average energy flux density for bare soil surface in August, 2014.

Figure 7. The average energy flux density for vegetation-covered soil surface in August, 2014.

Figure 8. The comparison of the surface temperature on a clear day, August 2nd, 2014.

Figure 9 shows the bare and vegetation-covered surface temperature comparison on an overcast day. Just as on a clear day, the daytime surface temperature still varies closely in step with the change of solar radiation. As on a clear day, the soil surface temperature is still higher than the vegetation-covered surface temperature. The temperature difference between these two surfaces on a clear day is much higher than that on an overcast day.

Figure 9. The comparison of the surface temperature on an overcast day, August 25th, 2014.

**The Effects of Colour, Soil Depth and Plant Type on Surface Temperature**

One of the goals that green roofs can achieve is to mitigate the heat island effect. The key to bringing down the heat island effect is reducing the surface temperature.

As stated in the bare soil surface temperature mathematical model, shown in Equations 21 and 22, $I_{\text{solar}}, T_{\text{sky}}, T_{\text{air}}, h_c, V$ are variables that cannot be...
controlled. But $\alpha_{solar}$, $\varepsilon_{surf}$, $d$ are variables that can be controlled by green roof designers. $\alpha_{solar}$ and $\varepsilon_{surf}$ are determined by surface color and texture. Soils have similar textures, so the color of the soil is something the designers can more easily control. Soil depth $d$ is also controlled by green roof designers.

Because $\varepsilon_{surf}$ is proportional to $\alpha_{solar}$, and they are both determined by the color of the surface, I used the solar absorption level, $\alpha_{solar}$, as the indicator to see how the color of the surface affects the surface temperature.

Figures 10 and 11 show the effects of the surface colour and the soil depth on the surface temperature on a clear day and on an overcast day. On a clear day in summer, between sunrise and sunset, the surface temperature of the bare soil is higher than the air temperature. When $\alpha_{solar}$ increases by 33%, the soil surface temperature rises about 10°C during peak solar radiation at noon. However, when $d$ increases by 50%, the surface temperature only rises about 2°C during peak solar radiation at noon. In addition, Figure 10 shows that, the higher the solar radiation, the more influential $\alpha_{solar}$ and $d$. During the night, the surface temperature is lower than the air temperature and the $\alpha_{solar}$ has no impact on surface temperature. Also, the thicker the soil the lower the surface temperature, which is the opposite of the effect during the daytime.

On an overcast day in summer, as on a clear day, Figure 11 shows that $\alpha_{solar}$ is still the primary influence on the surface temperature. When $\alpha_{solar}$ increases by 33%, the soil surface temperature rises about 5°C at peak solar radiation. On an overcast day, the peak solar radiation does not necessarily happen at noon, because it is also influenced by cloud conditions. When soil depth $d$ increases by 50%, the surface temperature rises less than 1°C. During the night, the effect of $\alpha_{solar}$ and $d$ on the bare soil surface under overcast conditions is similar to that on a clear day.

For vegetation-covered surfaces, as shown in Equation 37, $I_{solar}$, $T_{sky}$, $T_{air}$, $h_c$, $V$, $h$ are fixed by natural conditions. But $\alpha_{solar}$, $\varepsilon_{canopy}$, $d$, $r_1$, $W$, and $D$ are controlled by green roof designers. The vegetation color and texture determine $\alpha_{solar}$ and $\varepsilon_{canopy}$. The leaves have similar textures, so the color of the leaves is what the designers are concerned with. The green roof designers decide the soil depth $d$ with the needs of the plants in mind. Internal leaf resistance $r_1$ is in a range of 100-2000 s/m. The level of $r_1$ is determined by the type of plant. 200 s/m is the most common internal leaf resistance, but plants that thrive in relatively arid conditions have a higher internal leaf resistance. The dimension of a leaf is $W$ and $D$, which represents the size of the leaves, have influence on surface temperature too.

The surface temperatures of three plants with different internal leaf resistances and sizes on a clear day are shown in Figure 12. The sedum, which requires the least amount of maintenance and survives in harsh conditions, has the highest temperature. A native plant with the same internal leaf resistance as the grass is cooler than the grass because of its larger leaf size. However, on a cloudy day, as shown in Figure 13, the difference was minimal during the day, and there was no difference at night. At the time with low solar radiation, the surface temperature is even lower than the air temperature.

Conclusion

With the energy model proposed in this paper, three green roof elements - surface colour, soil depth and plant type - can be used to reduce surface temperature.

Reducing the solar absorption of a roof surface is the key to lowering the surface temperature during the day. Especially in a high-radiation environment, the colour of the surface affects solar absorption. The lighter the colour, the lower the surface temperature.

Minimizing the soil depth also reduces the surface temperature in warm weather. In a high-radiation environment, the surface temperature is higher than the soil temperature. A shallower soil stores less heat and therefore keeps the surface temperature lower.

The latent heat transferred by evapotranspiration reduces the surface temperature of the vegetation. Therefore, increasing the evaporation rate cools down the green roof surface. A plant with lower internal leaf resistance and larger leaf size has a higher evaporation rate. The native plant performs best in reducing surface temperature; the grass performs second-best; and the worst-performing is the sedum.

For the tested climate, a lighter colour, shallower soil layer, and plants with lower internal leaf resistance and larger leaf will work best to reduce the heat island effect.
